Clinical Pharmacogenetics Implementation Consortium Guideline for Cytochrome P450 (CYP)2D6 Genotype and Atomoxetine Therapy

Jacob T. Brown1, Jeffrey R. Bishop2, Katrin Sangkuhl3, Erika L. Nurmi4, Daniel J. Mueller5,6, Jean C. Dinh7, Andrea Gaedigk7,8, Teri E. Klein3, Kelly E. Caudle9, James T. McCracken4, Jose de Leon10 and J. Steven Leeder7,8,*

Atomoxetine is a nonstimulant medication used to treat attention-deficit/hyperactivity disorder (ADHD). Cytochrome P450 (CYP)2D6 polymorphisms influence the metabolism of atomoxetine thereby affecting drug efficacy and safety. We summarize evidence from the published literature supporting these associations and provide therapeutic recommendations for atomoxetine based on CYP2D6 genotype (updates at www.cpicpgx.org).

The purpose of this guideline is to provide information to allow the interpretation of clinical CYP2D6 genotype tests so that the results can be used to guide the use of atomoxetine. Detailed guidelines for prescribing of atomoxetine as well as analyses of cost-effectiveness are beyond the scope of this document. The Clinical Pharmacogenetic Implementation Consortium (CPIC) guidelines are periodically updated at https://cpicpgx.org/guidelines and http://www.pharmgkb.org.

FOCUSED LITERATURE REVIEW

A systematic literature review focused on CYP2D6 genotype and atomoxetine use was conducted (details in Supplement).

GENE: CYP2D6

CYP2D6 is highly polymorphic with over 100 known allelic variants and subvariants identified (www.PharmVar.org; CYP2D6 Allele Definition Table1,2). CYP2D6 alleles have been extensively studied in multiple geographically, racially, and ethnically diverse groups, and significant differences in allele frequencies have been observed (CYP2D6 Allele Frequency Table1,2). The most commonly reported alleles are categorized into functional groups as follows: normal function (e.g., CYP2D6*1, *2, and *35), decreased function (e.g., CYP2D6*9, *10, *17, *29, and *41), and no function (e.g., CYP2D6*3−*6).3,4 Because CYP2D6 is subject to deletions and gene duplications or multiplications, many clinical laboratories also report copy number variations. CYP2D6*5 represents a gene deletion (no function allele) whereas gene duplications and multiplications are denoted by “xN” (e.g., CYP2D6*1xN with “xN” representing the number of CYP2D6 gene copies). Alleles carrying two or more normal function gene copies are categorized as alleles with increased function.

The combination of alleles is used to determine a patient’s genotype. Each functional group is assigned an activity value ranging from 0–1 (e.g., 0 for no, 0.5 for decreased, and 1.0 for normal function).4 If an allele contains multiple copies of a functional gene, the value is multiplied by the number of copies present. Thus, the CYP2D6 activity score (AS) is the sum of the values assigned to each allele, which typically range from 0−3.0 but may exceed 3.0 in rare cases.4

The CYP2D6 AS can be translated into a standardized phenotype classification system (CYP2D6 Allele Definition Table1,2): patients with an AS of 0 are poor metabolizers (PMs), those with a score of 0.5 are considered intermediate metabolizers (IMs), those with a score of 1.0–2.0 represent normal metabolizers (NMs), and patients with a score > 2 are classified as ultrarapid metabolizers (UMs). However, diplotypes with an AS of 1.0 give rise to less activity toward certain drugs, including tamoxifen and atomoxetine compared with those with an AS of 1.5 or 2.0; therefore, patients with an AS of 1.0 may be classified as IMs by some reference laboratories. Thus, for this guideline, an AS of 1.0 is classified as a CYP2D6 NM or IM (Table 1). This is in contrast to the classification used in some previous guidelines5,6 but similar to the recently published guideline on CYP2D6 and tamoxifen.7 Note that genotypes with an AS of 1 are classified as NMs in the CYP2D6 Genotype-to-Phenotype Table1, and CPIC will update the CPIC website and this table if needed. Efforts to standardize CYP2D6 genotype-to-phenotype translation system are ongoing. Currently, a CYP2D6 Genotype-to-Phenotype

AS, activity score; CYP, cytochrome P450.

\(^a\)Assignment of allele function and citations for allele function can be found https://www.pharmgkb.org/page/cyp2d6RefMaterials (CYP2D6 Allele Definition Table and CYP2D6 Allele Functionality Table\(^1,2\)). For a complete list of CYP2D6 diplotypes and resulting phenotypes, see the CYP2D6 Genotype to Phenotype Table\(^1,2\).

Note that genotypes with an AS of 1 are classified as normal metabolizers in the online CYP2D6 genotype to phenotype table.\(^2\)See the CYP2D6 Frequency Table for race-specific allele and phenotype frequencies or see Gaedigk et al.\(^1,2,3,7\) Where \(xN\) represents the number of CYP2D6 gene copies. For individuals with CYP2D6 duplications or multiplications, see supplemental data for additional information on how to translate diplotypes into phenotypes.\(^5\)Patients with an AS of 1.0 may be classified as intermediate metabolizers by some reference laboratories. A group of CYP2D6 experts are currently working to standardize the CYP2D6 genotype-to-phenotype translation system. The Clinical Pharmacogenetic Implementation Consortium (CPIC) will update the CPIC website accordingly (CYP2D6 Genotype to Phenotype Table\(^1,2)\).

Working Group is also reviewing the classification of the decreased function CYP2D6*10 allele (discussions regarding the accuracy of CYP2D6*10 classification using a value of 0.5 for AS calculation have been ongoing for years\(^2\)). This allele seems to convey a reduction in activity across many substrates, which led to a special recommendation for CYP2D6*10-containing diplotypes for tamoxifen and for atomoxetine (Table 2).

It is important for reference laboratories providing clinical CYP2D6 genotyping to use varying methods to assign phenotypes. Therefore, it is advisable to note a patient’s CYP2D6 diplotype and to calculate the AS before making therapeutic decisions about atomoxetine therapy. See the CYP2D6 Diplopteto-Phenotype Table for a comprehensive translation of diplotype to phenotype.\(^1,2\)

**Genetic test interpretation**

Clinical laboratories rarely sequence through the CYP2D6 gene or interrogate every known variant position. Instead, they typically test for variants that are used to determine common allele haplotypes using the star-allele (*) nomenclature system. Allele definitions are maintained by the Pharmacogene Variation Consortium (www.PharmVar.org). The CYP2D6 Allele Definition Table and CYP2D6 Allele Functionality Table and tables found on the PharmGKB website contain a list of CYP2D6 alleles,\(^1,2\) the specific combination of variants that can be used to determine the allele, functional status, and frequency across major ethnic populations as reported in the literature.

Genetic test results are reported as diplotypes or the combination of the maternal and paternal alleles (e.g., CYP2D6*1/*2). Phenotypes are assigned based on the reported CYP2D6 diplotype, as summarized in Table 1 and in the CYP2D6 Dip Table.

The limitations of genetic testing as described here include: (i) rare variants are often not detected, (ii) known star alleles (*), which are not tested by a specific laboratory will not be reported, and instead, the patient will be reported as a *\(i\), and (iii) most tests are not designed to detect unknown or \textit{de novo} variants.

**Supplemental Material** (Genetic Test Interpretation Section) contains additional information regarding CYP2D6 genetic test interpretation and phenotype assignment.

**Available genetic test options**

**Incidental findings**

Currently, there are no diseases or conditions that have been consistently linked to variation in the CYP2D6 gene independent of drug metabolism and response.

**Other considerations**

CYP2D6 is the primary enzyme responsible for the metabolism of many other commonly used medications. It is important to note that variation in CYP2D6 may have implications for other therapies that are beyond the scope of this guideline. CPIC guidelines exist for other drugs metabolized by CYP2D6.\(^3,6,9\)

**DRUGS: ATOMOXETINE**

**Background**

Based on a parent-reported survey in 2016, an estimated 6.1 million children (9%) between the ages of 2 and 17 years received a diagnosis of ADHD.\(^10\) Although not a first-line agent for the treatment of ADHD, atomoxetine was the first nonstimulant medication approved in the United States to treat ADHD in 2002. Originally developed in the 1980s to treat adult depression, but only approved for the treatment of ADHD, atomoxetine is a selective norepinephrine reuptake inhibitor.\(^11\) A surge in atomoxetine prescriptions occurred following its approval, peaking

ADHD, attention-deficit/hyperactivity disorder; AS, activity score; CYP, cytochrome P450.

²Rating scheme described in the Supplement.
³Therapeutic range of 200–1000 ng/mL has been proposed.
⁴Limited data are available regarding the relationship between atomoxetine plasma concentrations and clinical response. Available information suggests that clinical response is greater in poor metabolizers compared to non-poor metabolizers and may be related to the higher plasma concentrations 1–1.5 hours after dosing in poor metabolizers compared with non-poor metabolizers administered a similar dose. Furthermore, modest improvement in response, defined as reduction in ADHD rating scale (RS), is observed at peak concentrations > 400 ng/mL. The Clinical Pharmacogenetic Implementation Consortium (CPIC) has general classified patients with AS of 1 as “NM.” However, in the case of atomoxetine, prescribing recommendations for those with an AS of 1.0 are allele-dependent, based on the presence of the CYP2D6*10 allele.
in 2004 when it was the third most commonly prescribed med-
ication for ADHD after methylphenidate and amphetamine/ 
dextroamphetamine; however, following 2004, prescriptions 
gradually decreased to around 2 million per year in 2010.12
Unlike stimulants, atomoxetine has a delayed onset to clinical 
effect and typically takes 2–4 weeks for full impact on symptoms 
to be observed.13
Atomoxetine is an active parent compound and is metabolized 
by CYP2D6 to an active metabolite, 4-OH-atomoxetine; how-
ever, this metabolite is rapidly glucuronidated to the inactive 4-
OH-atomoxetine-O-glucuronide, and the unconjugated metabo-
lite circulates at concentrations ~ 100-fold lower than the parent 
compound.14,15 To a lesser extent, atomoxetine is also metabolized 
by CYP2C19 to N-desmethylatomoxetine, which is subsequently 
metabolized via CYP2D6 to N-desmethyl-4-hydroxyatomoxetine 
(Figure 1).
The recommended initial daily dose of atomoxetine is 
0.5 mg/kg in children and adolescents up to 70 kg with a tar-
get and maximum dose of 1.2 mg/kg/day and 1.4 mg/kg/day, 
respectively. In children and adolescents over 70 kg and adults, 
the initial daily dose of atomoxetine is 40 mg/day, with a target 
and maximum daily dose of 80 mg/day and 100 mg/day, respec-
tively (according to the product labeling). In patients taking 
a CYP2D6 inhibitor or those who are known to be CYP2D6 
PMs, the product labeling currently recommends starting ther-
apy at the usual daily dose and increasing to the recommended 
target doses if the drug is well tolerated and symptoms fail to 
prove after 4 weeks.
In registry clinical trials for the efficacy and safety of atomox-
etine, separation from placebo was, on average, observed after 
1–2 weeks of treatment.13 Incremental increases in response 
may occur for up to 24 weeks or longer. Pharmacokinetic studies 
highlight that doses producing atomoxetine peak concentrations 
> 200 ng/mL 1–4 hours after dosing may increase the likelihood 
of response.16 Common dose-related side effects from atomoxetine 
occuring more frequently in CYP2D6 PMs compared to non-
PMs in children or adults include dry mouth, blurred vision, sleep 
disturbances, decreased weight or appetite, constipation, depres-
sion, tremor, feeling jittery, excoriation, dry eye or conjunctivitis, 
synecope, urinary retention, sexual dysfunction, hyperhidrosis, pe-
ripheral coldness, and elevated blood pressure.16

Linking genetic variability to variability in drug-related 
phenotypes

Atomoxetine pharmacokinetics. A strong association exists 
between CYP2D6 genotype and atomoxetine pharmacokinetic 
variability (see Table S1). Atomoxetine is considered a 
CYP2D6 “sensitive substrate” by the US Food and Drug 
Administration (FDA) for evaluating drug–drug interactions. 
As such, CYP2D6 genetic variation has a profound effect on 
atomoxetine pharmacokinetics.17 The range of values observed

![Figure 1. Atomoxetine pathway, pharmacokinetics. Data observed from ref. 36. Image reproduced and is licensed under CC BY-SA 4.0 from PharmGKB. CYP, cytochrome P450.](image-url)
for atomoxetine exposure, most often reported as either the area under the drug plasma concentration-time curve (AUC) or the maximum concentration ($C_{\text{max}}$), is substantial. Atomoxetine exposure (AUC) is, on average, 10-fold higher in CYP2D6 PMs compared to non-PMs. However, the comparison of group mean values obscures the full range of exposures that may be present in a population. For example, a CYP2D6 genotype-stratified single-dose pharmacokinetic study ($n = 23$ children) observed a 30-fold range in AUC when dosed using the FDA-recommended initial dose of 0.5 mg/kg. Decreasing atomoxetine exposure was associated with genotype (i.e., increasing CYP2D6 AS). It should be noted that in early in vivo drug development studies, the depth of genotyping only differentiated between CYP2D6 PMs and non-PMs. Subsequent studies that performed more comprehensive genotyping suggest that CYP2D6 IMs (e.g., a CYP2D6 AS of 0.5) have pharmacokinetic profiles that differ from both PMs and NMs.

Ex vivo studies evaluating metabolic capacity in human liver microsomes that have been genotyped for CYP2D6 provide evidence that increased exposure is due to reduced metabolic capacity in both IMs and PMs. The most studied decreased function CYP2D6 allele in the context of atomoxetine is the CYP2D6*10 variant. Individuals with two CYP2D6*10 alleles had higher atomoxetine exposure (5-fold higher peak concentration) when compared with individuals with at least one normal function allele. Individuals heterozygous for *10 and one fully functional CYP2D6 allele had higher atomoxetine exposure compared with individuals carrying two fully functioning alleles.

**Atomoxetine response/toxicity.** The likelihood of favorable treatment response and side effects are both reported to be higher in CYP2D6 PMs compared to non-PMs, which is likely due to increased exposure to the parent drug in the PMs. The extent of improvement in ADHD symptoms (i.e., mean change in ADHD symptom rating scale scores), was greater in PMs compared to non-PMs, whereas CYP2D6 non-PMs were also more likely to discontinue atomoxetine therapy due to inefficacy as compared with CYP2D6 PMs. Current evidence is limited to comparisons between CYP2D6 PMs and non-PMs; thus, there is no evidence correlating efficacy and/or drug discontinuation with other CYP2D6 phenotype classes. Higher exposures to atomoxetine may also partially explain a greater percentage of side effects in CYP2D6 PMs, such as increases in heart rate and diastolic blood pressure, when compared with non-PMs. However, in a retrospective study that evaluated atomoxetine response in participants enrolled from six atomoxetine randomized controlled trials ($n = 618$), beneficial response was noted in 47% of patients, 13% of patients were determined to have minimal response, and 40% had no response. These data suggest at least two distinct atomoxetine response groups within the observed population. Additionally, it can also be inferred that CYP2D6 genotype alone does not account for the atomoxetine response distribution described in the above investigation, given that CYP2D6 PMs frequency is ~ 5–10% of the population (CYP2D6 Frequency Table).

The most well-studied pharmacokinetic parameter for atomoxetine relates plasma drug concentrations that approximate the $C_{\text{max}}$ of the parent compound to reduction of ADHD symptoms. Given this evidence, the therapeutic recommendation for each CYP2D6 phenotype class also includes guidance for plasma drug concentration testing, as a means to estimate atomoxetine exposure (i.e., exposure check). These target reference values are from the Consensus Guidelines for Therapeutic Drug Monitoring in Neuropsychopharmacology and are meant to guide the clinician in the event that patient response to atomoxetine is inadequate. Included with these guidelines is a plasma concentration (henceforth described as an "exposure check") performed post-drug administration, which is included to rule out inadequate systemic exposure as a cause of nonresponse in individuals with a CYP2D6 AS of 1 or more. This CPIC guideline also includes a grading system to evaluate the strength of evidence between various CYP2D6 genotype-predicted phenotypes and the corresponding therapeutic recommendation. Data from both in vitro and in vivo studies (Table S1), as well as consensus recommendations, were used in formulating the guidance in **Table 2**.

**Therapeutic recommendations**

**Tables 2 and 3** summarize the therapeutic recommendations for atomoxetine based on CYP2D6 phenotype in children and adults, respectively. Although not routinely ordered, patients may benefit from a single time point atomoxetine exposure check to guide therapy. Exposure check concentrations between 200 and 1,000 ng/mL are generally considered to be "therapeutic," however, for individuals with comorbidities a higher exposure target may be warranted, as was done in a study evaluating children with both ADHD and oppositional defiant disorder.

We propose that the plasma concentration exposure check be used with an individual's CYP2D6 genotype to help clinicians guide dose selection and titration, as discussed below. Based on pharmacokinetic knowledge that CYP2D6 metabolism phenotypes influence atomoxetine peak concentration and half-life, **Tables 2 and 3** propose that prescribers consider measuring peak concentrations 1–2 hours after dosing in known CYP2D6 UMs, NMs, and IMs with high activity (AS 1.0 without a CYP2D6*10 allele), 2–4 hours after dosing in CYP2D6 IMs with low activity (AS 0.5) and in individuals with AS of 1 when the CYP2D6*10 allele is present, and 4 hours after dosing in PMs.

Very limited data exist for CYP2D6 UMs taking atomoxetine, but it is unlikely these individuals would achieve adequate serum concentrations with standard atomoxetine dosing. As discussed above, CYP2D6 non-PMs have a lower likelihood of treatment response as compared with CYP2D6 PMs. Thus, for CYP2D6 UMs and NMs, recommendations are to initiate standard atomoxetine dosing (see **Tables 2 and 3** for pediatric and adult dosing, respectively), and if no clinical response is observed after 2 weeks, consider obtaining a peak plasma concentration 1–2 hours after dose administration. If the peak concentration is < 200 ng/mL, consider increasing the dose proportionally to

This may increase the occurrence of treatment-emergent side effects, but also a greater improvement of ADHD symptoms as compared with non-poor metabolizers in those who tolerate treatment. Poor metabolizer status is associated with lower final dose requirements as compared to non-poor metabolizers.</td>
<td>Initiate with a dose of 40 mg/day and if no clinical response and in the absence of adverse events after 2 weeks increase dose to 80 mg/day. If response is inadequate after 2 weeks, consider obtaining a plasma concentration 2–4 hours after dosing. If concentration is &lt; 200 ng/mL, consider a proportional dose increase to achieve a concentration to approach 400 ng/mL. If unacceptable side effects are present at any time, consider a reduction in dose.</td>
<td>Moderate</td>

ADHD, attention-deficit/hyperactivity disorder; AS, activity score; CYP, cytochrome P450.

*Rating scheme described in the Supplement. *Therapeutic range of 200–1,000 ng/mL has been proposed. **Limited data are available regarding the relationship between atomoxetine plasma concentrations and clinical response. Available information suggests that clinical response is greater in poor metabolizers compared with non-poor metabolizers and may be related to the higher plasma concentrations 1–1.5 hours after dosing in poor metabolizers compared with non-poor metabolizers administered a similar dose. Furthermore, modest improvement in response, defined as reduction in ADHD-rating scale (RS), is observed at peak concentrations > 400 ng/mL. b Doses above 120 mg/day have not been evaluated. The Clinical Pharmacogenetic Implementation Consortium (CPIC) has general classified patients with an AS of 1 as “NM.” However, in the case of atomoxetine, prescribing recommendations for those with an AS of 1.0 are allele-dependent, based on the presence of the CYP2D6*10 allele.
approach 400 ng/mL. It is important to note that doses above 120 mg have not been extensively evaluated, although they may be necessary to achieve target concentrations in some patients. Although CYP2D6 NMs with an AS of 1 (without the presence of the CYP2D6*10 allele) have higher atomoxetine plasma concentrations compared with NMs with an AS of 2, the clinical significance of this difference is unclear. Thus, CYP2D6 NMs with an AS of 1 (without the presence of the CYP2D6*10 allele) should be treated similarly to CYP2D6 NMs with an AS of 2.

CYP2D6 PMs, IMs, and NMs with an AS of 1 in the presence of the CYP2D6*10 allele have significantly decreased metabolism of atomoxetine, which may increase the risk of side effects. However, these individuals may also have greater improvement of ADHD symptoms and lower dose requirements as compared with non-PMs. Therefore, the recommendation for these phenotype groups is to initiate with a standard starting dose (see Tables 2 and 3 for pediatric and adult dosing, respectively), and if there is an inadequate trajectory of symptom improvement after 2 weeks (in the absence of side effects), consider obtaining a plasma concentration 2–4 hours after dosing. If response is inadequate and side effects are not present, consider adjusting the dose proportionally to approach 400 ng/mL.

**Recommendations for incidental findings**

Not applicable.

**Other considerations**

In addition to CYP2D6, variation in atomoxetine response has also been examined with its pharmacodynamic target, the norepinephrine transporter, SLC6A2. Ramoz et al. describes significant associations between 20 single-nucleotide polymorphisms within SLC6A2 and responders as compared with nonresponders of atomoxetine. If other studies replicated this finding, future guidelines may consider incorporating this result in its recommendations.

Individuals taking atomoxetine along with a strong CYP2D6 inhibitor (e.g., bupropion, fluoxetine, and paroxetine) may experience higher than expected concentrations based on their CYP2D6 genotype through a process known as phenocconversion. This has been described for paroxetine and fluoxetine in non-PM metabolizers taking atomoxetine. For the duration of the phenocconversion (for fluoxetine it may last up to 2–3 months after fluoxetine discontinuation in average patients and longer in some individuals), the individual phenotypically resembles a CYP2D6 PM regardless of genotype.

**Implementation resources for this guideline.** The guideline supplement contains resources that can be used within electronic health records to assist clinicians in applying genetic information to patient care for the purpose of drug therapy optimization (see Resources to incorporate pharmacogenetics into an electronic health record with clinical decision support section in the supplement). Clinical implementation resources include cross-references for drug and gene names to widely used terminologies and standardized nomenclature systems, workflow diagrams, a table that translates genotype test results into a predicted phenotype with genetic test interpretation, and an example text for documentation in the electronic health records and point-of-care alerts.

**POTENTIAL BENEFITS AND RISKS FOR THE PATIENT**

The potential benefit of using an individual’s CYP2D6 genotype to guide atomoxetine dosing is that clinicians can be alerted to individuals who are more likely to fail treatment at standard dosing (e.g., NMs or UMs) or be at an increased risk of adverse effects (e.g., PMs). The FDA recommends atomoxetine doses up to 100 mg/day in adults or 1.2 mg/kg/day in children. This guideline proposes that CYP2D6 UMs (AS > 1–2% of US patients) and NMs (AS 1–2 and 77–92% of US patients) may need higher than FDA-recommended doses to achieve concentrations associated with clinical response, based on low atomoxetine peak concentrations (< 200 ng/mL). It is estimated that up to one of three of US patients may be in this category of needing higher than recommended doses, but the exact prevalence needs to be established by future clinical studies. A potential risk of testing is the misinterpretation of genetic test results, as rare or novel variants are typically not interrogated. If an individual carries a rare variant, the actual phenotype may differ from the phenotype predicted by the genotypes included on a specific laboratory test. An individual’s intrinsic CYP2D6 activity may also be impacted by other factors, including epigenetics, diet, comorbidities, or co-medications. Any of these factors, including the comedication with a CYP2D6 inhibitor, would be reflected through atomoxetine therapeutic drug monitoring. Although CYP2D6 genotyping is usually reliable when performed in qualified laboratories, the possibility for error in genotyping, contamination, or mislabeling of the sample remains.

**CAVEATS: APPROPRIATE USE AND/OR POTENTIAL MISUSE OF GENETIC TESTS**

Rare CYP2D6 variants may not be included in the genotype testing used by some laboratories, and patients with rare variants may be assigned a “wild-type” (CYP2D6*1) genotype by default. Thus, there is a small risk that an assigned “wild-type” allele could potentially harbor a no or decreased function variant. Furthermore, it is important that the genetic testing platform includes testing for gene copy number to identify CYP2D6 ultrarapid metabolizers or gene deletions that may decrease CYP2D6 AS. Caution should be used regarding molecular diagnostics of CYP2D6 gene copy number variation because commercially available genotyping results may differ between diagnostic laboratories depending on assay design. Like all diagnostic tests, CYP2D6 genotype is one of multiple pieces of information that clinicians should consider when making their therapeutic choice for each patient. Furthermore, there are several other factors that cause potential uncertainty in the genotyping results and phenotype predictions. These are discussed in detail in the Supplemental Material online.

In this guideline, we propose that exposure be assessed to guide subsequent dosing decisions when the desired clinical response has not been achieved, but we also recognize that this recommendation has limitations: available exposure-response data from clinical trials are derived from concentrations drawn 60–90 minutes...
after dosing; although this measure may not be the best predictor of response, the relationship between other exposure measures, such as trough concentration at steady state, steady-state AUC, unbound atomoxetine concentrations, or total active compounds (unbound atomoxetine + unbound 4-OH aglycone), has not been evaluated.
