CPIC UPDATES

Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines are published in full on www.cpicpgx.org. Information will be reviewed and updated periodically on that website.

LITERATURE REVIEW

For TPMT, we searched the PubMed database from 1966 to October 2012 for the original guideline and then Oct 1, 2012 to June 6, 2017 for this guideline update for keywords ((TPMT) AND ((TPMT) AND thiopurine) AND ((TPMT) AND azathioprine) AND ((TPMT) AND mercaptopurine) AND ((TPMT) AND thioguanine)) for the contribution TPMT genotype and phenotype had on predicting a thiopurine-related adverse drug event (ADE) or outcome. Using these search terms, 139 publications were identified and following application of the inclusion criteria 133 were reviewed and included in the evidence table (Table S1).

For NUDT15, we searched the PubMed database (no start date to May 25, 2017) for keywords (NUDT15) for the contribution NUDT15 genotype had on predicting a thiopurine-related adverse drug event (ADE) or outcome. Using these search terms, 41 publications were identified and following application of the inclusion criteria, 21 were reviewed and included in the evidence table (Tables S2).

To construct a TPMT minor allele frequency table based on ethnicity, PubMed was searched up to 1/31/2018. Studies were considered for inclusion if: (1) the ethnicity of the population was clearly indicated and (2) allele frequencies for TPMT genotypes were reported. Additionally, allele frequencies reported in the gnomAD browser (http://gnomad.broadinstitute.org/ - exomes and genomes) and ensembl (grch37.ensembl.org - exomes or genomes) were also included. Many TPMT allele frequencies could not be found through a PubMed search, so the gnomAD frequencies were the only frequencies available for many alleles. The same approach was used for NUDT15 allele frequencies. Very little allele frequency information could be found.
through a PubMed search, so gnomAD and ensembl allele frequencies were used for several population groups.

**GENETIC TEST INTERPRETATION**

The haplotype, or star (*) allele name, is determined by a specific SNP or a combination of SNPs that are interrogated in the genotyping analysis. The genotypes that constitute the haplotype, or star (*) alleles for TPMT and NUDT15, and the rs# for each of the specific genomic nucleotide alterations that define the alleles (if available), are described in the **TPMT Allele Definition Table** and **NUDT15 Allele Definition Table** found at https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt/.

For TPMT, the genotype results are generally reported as a diplotype, which includes one maternal and one paternal star allele (e.g., *1/*3A). The TPMT activity associated with each of the common * alleles is summarized in **TPMT Allele Functionality Table** (1, 2); https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt/). The most common no function allele among Caucasians for TPMT is designated as *3A; other alleles predominate in other ethnic/ancestral groups (see **TPMT Frequency Table**; https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt) (1, 2). The *3A allele designation for TPMT is assigned based on the SNP genotypes and the very strong linkage disequilibrium that has been established between two of the most common inactivating TPMT SNPs: Ala154Thr (rs1800460; c.460G>A) and Tyr240Cys (rs1142345; c.719A>G); when the rare genotype is present at these two SNP positions in the heterozygous state, the assumption is that the rare genotypes are in cis (on the same allele) and the diplotype call is *1/*3A. However, each of these SNPs have been observed to exist on their own allele (*3B and *3C, respectively) in some populations (**TPMT Frequency Table**; https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt)(1, 2) with the rare genotypes present on their own; if these rare genotypes are present on opposite alleles in the same individual, the diplotype call should be that of a compound heterozygote diplotype (*3B/*3C)—a call consistent with homozygous TPMT deficiency. If one assumes that the frequency of the *3B-defining variant in Caucasians is 0.0063, and of the *3C-defining variant is 0.004205, the probability of finding such a
compound heterozygote deficient diplotype is estimated 1 in 515,861 Caucasian individuals. It is controversial whether an individual with the *3B/*3C genotype has ever been identified (3, 4), but the *3B allele is very rare, and given the frequency of *3C, a very large sample size would be needed to have a high probability of detecting the *3B/*3C diplotype. Phenotypic tests could distinguish between the *1/*3A and the *3B/*3C diplotypes and should be employed if a homozygous deficient genotype is suspected. One of the two phenotyping tests (measuring erythrocyte TPMT activity or thiopurine metabolites after thiopurine dosing) can differentiate a *1/*3A diplotype (TPMT intermediate metabolizer) from a very rare *3B/*3C diplotype (TPMT poor metabolizer). TPMT activity would be extremely low in the latter case and intermediate in the former case; erythrocyte thiopurine metabolites would indicate a low but detectable MeTIMP/TGN ratio for a *1/*3A diplotype and the *3B/*3C diplotype would be consistent with undetectable MeTIMP (or MeMPN) levels.

For NUDT15, there have been nine * alleles (haplotypes) reported thus far based on seven known variants (2 indels and 5 SNPs). The p.R139C (rs116855232; c.415C>T) variant is the most common polymorphism and can be observed either alone (*3 allele) or together with the p.V18_V19dup (rs869320766; c.50_55dup) variant as a distinctive haplotype (*2 allele). No significant linkage disequilibrium is present amongst other NUDT15 variants and all other *alleles are defined by a single variant. The p.V18_V19ins variants can be present without the p.R139C SNP (*6 allele) but is exceedingly rare based on the 1000 Genomes data. In East Asians for whom NUDT15 variants are more common, 6.0% of individuals are heterozygous for both the p.R139C and the p. V18_V19insGV variants, of which 5.8% are *1/*2 and 0.2% are *3/*6. Therefore, while it is advisable to resolve *1/*2 vs *3/*6 diplotypes, the probability for the former is overwhelming. The p.R139H (rs147390019; c.416G>A) variant that defines the *4 allele is only one base pair from the p.R139C variant. Thus, genotyping can be challenging in patients heterozygous for both variants because of interference between the two (e.g., during PCR amplification and/or probe hybridization). However, *3/*4 is exceedingly rare (0.01% in East Asians or Hispanics).
AVAILABLE GENETIC TEST OPTIONS
Commercially available genetic testing options change over time. Below is some information that may assist in evaluating options.

Desirable characteristics of pharmacogenetic tests, including naming of alleles and test report contents, have been extensively reviewed by an international group, including CPIC members (5). CPIC recommends that clinical laboratories adhere to these test reporting standards. CPIC gene-specific tables (see Allele Definition Table, Allele Functionality Table and Frequency Table (https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt/)) adhere to these allele nomenclature standards (5). Moreover, the Allele Definition, Functionality, and Frequency Tables may be used to assemble lists of known functional and actionable pharmacogenetic variants and their population frequencies, which may inform decisions as to whether tests are adequately comprehensive in interrogations of alleles.

For TPMT, it has been demonstrated that the vast majority of low-activity phenotypes are accounted for by the three SNPs that constitute the *2, *3A, *3B, and *3C alleles, and that sequencing yields few new important low-function variants (6, 7). For NUDT15, it is not yet clear the extent to which multiple rare variants may account for low NUDT15 activity, and thus the need for sequencing-based approaches cannot be ignored.

The Genetic Testing Registry (GTR) provides a central location for voluntary submission of genetic test information by providers and is available at http://www.ncbi.nlm.nih.gov/gtr/.

Many commercially available tests for TPMT include only *2, *3A, *3B and *3C, although the rare *4 allele is also inactivating. Many methods are available for more comprehensive TPMT genotyping of additional alleles (8), and some are being adapted for clinical use.
There is an increasing demand for NUDT15 tests which are now already available at a number of commercial laboratories. The p.R139C (rs116855232) variant is most commonly tested but some assays can determine *1-*6 alleles.

LEVELS OF EVIDENCE LINKING GENOTYPE TO PHENOTYPE
The evidence summarized in Table S1 and S2 is graded using a scale modified slightly from Valdes et al. (9)

High: Evidence includes consistent results from well-designed, well-conducted studies.

Moderate: Evidence is sufficient to determine effects, but the strength of the evidence is limited by the number, quality, or consistency of the individual studies; generalizability to routine practice; or indirect nature of the evidence.

Weak: Evidence is insufficient to assess the effects on health outcomes because of limited number or power of studies, important flaws in their design or conduct, gaps in the chain of evidence, or lack of information.

STRENGTH OF DOSING RECOMMENDATIONS
CPIC’s dosing recommendations are based on weighting the evidence from a combination of preclinical functional and clinical data (Tables S1 and S2), as well as on some existing disease-specific consensus guidelines (10, 11). Some of the factors that are taken into account in evaluating the evidence supporting dosage recommendations include: in vivo clinical outcome data for thiopurines, in vivo pharmacokinetic and pharmacodynamic data for thiopurines, in vitro enzyme activity of expressed wild-type or variant-containing TPMT or NUDT15 (with thiopurines or TGTP as substrate, respectively), in vitro TPMT enzyme activity from tissues isolated from individuals of known TPMT genotypes, in vivo pre-clinical pharmacokinetic and pharmacodynamic studies, and in vitro studies of TPMT or NUDT15 protein stability.

Overall, the therapeutic recommendations are simplified to allow rapid interpretation by clinicians. CPIC uses a slight modification of a transparent and simple system for just three categories for recommendations adopted from the rating scale for evidence-based recommendations on the use of antiretroviral agents (12):
**Strong** recommendation for the statement: “The evidence is high quality and the desirable effects clearly outweigh the undesirable effects.”

**Moderate** recommendation for the statement: “There is a close or uncertain balance” as to whether the evidence is high quality and the desirable clearly outweigh the undesirable effects.

**Optional** recommendation for the statement: The desirable effects are closely balanced with undesirable effects, or the evidence is weak or based on extrapolations. There is room for differences in opinion as to the need for the recommended course of action.

**No recommendation:** There is insufficient evidence, confidence, or agreement to provide a recommendation to guide clinical practice at this time.

**OTHER CONSIDERATIONS**
Complementary clinical laboratory tests are available to measure thiopurine metabolites in erythrocytes: TGNs (for mercaptopurine, azathioprine, and thioguanine) and MeMPNs (or MeTIMP) for those on mercaptopurine or azathioprine. These tests can be useful to confirm TPMT phenotype and to test for patient adherence with oral medication regimens, but the values are dependent upon the prior thiopurine dosing. TPMT phenotype can also be assessed by measuring erythrocyte TPMT activity; however, activity measures must be interpreted with caution because TPMT activity increases after exposure to thiopurines. Thus, TPMT measured at diagnosis may not reflect TPMT activity later in therapy. This is one reason the TPMT genotype is a useful measure, as genotype does not change during therapy. Although there may be some settings in which aminosalicylates affect TPMT activity, other studies clearly show no in vivo drug interactions. (13-17) TPMT may be spuriously altered from baseline if the patient has recently received allogeneic erythrocyte transfusions or if the patient has previously received an allogeneic hematopoietic stem cell transplant (10, 18-22). Furthermore, because TPMT activity is similar to other erythrocyte enzymes that decrease during the red cells’ life-span, the erythrocyte TPMT activity in a wild-type patient with bone-marrow insufficiency (e.g., as is true at diagnosis of ALL) may be within the expected range of a healthy TPMT heterozygote patient, and a TPMT heterozygous patient with a
rapid red cell turn-over (e.g. as seen during hemolysis) may have erythrocyte TPMT activity within the TPMT wild-type range. (23)

Conflicts between phenotype and genotype results (e.g. a low TPMT activity in an individual with a wild-type genotype) may be resolved with additional testing. Because most commercial genotyping assays test only the three most common inactivating SNPs, if a rare inactivating (and untested-for) SNP is present, a spurious wild-type genotype assignment could be made although phenotype tests indicate low TPMT activity or low MeTIMP/TGN ratio. Another rare possibility would be that two inactivating SNP variants are mistakenly assumed to reside on the same allele, when they in fact reside on opposite alleles; phenotypic tests can distinguish these two possibilities.

As indicated in the main manuscript, there is a wide variety of starting, target, and usual doses of thiopurines for different diseases (24, 25) or for the same disease by different groups (25, 26). Patients with an intermediate metabolizer TPMT phenotype will be more likely to require a thiopurine dosage decrease if the starting, target, or usual dosage is on the higher end of the usual range. Also, as indicated below, heterozygotes are more likely to need a decrease of their thiopurines if other concurrent therapy (such as methotrexate) has overlapping adverse effects (such as myelosuppression). Some have suggested that combining thiopurines with allopurinol minimizes methylated active metabolites (27-30), an interaction that will depend upon TPMT phenotype/genotype.

Because clinical assays for TGNs do not distinguish tri- from di- from mono-phosphates, TGN levels cannot be used to identify low NUDT15 activity. There is a growing body of research data indicating that thioguanine incorporated into blood cell DNA may be an indicator of NUDT15 status in patients receiving thiopurines (31), but there are not enough data at present to know if this assay will be a useful adjunct it were available in the clinic.

One caveat to thiopurine use is that some serious long-term adverse effects (secondary tumors) have been associated with defective TPMT activity (19, 32-34) without
necessarily causing serious acute myelosuppression; whether capping doses of thiopurines in those with a TPMT defect will decrease the risk of the late effect of secondary cancer is not known. It should be noted that at least one study did not confirm a relationship between TPMT and a higher risk of second tumors (35). Veno-occlusive disease and persistent splenomegaly have been associated with low TPMT activity in a UKALL trial, although not with TPMT genotype (36, 37), but VOD was not associated with TPMT genotype in a CCG trial (38). Thiopurine-associated pancreatitis has not been related to low TPMT activity, and hepatotoxicity (hypertransaminasemia) is more common in those with high TPMT activity (39-45).

Hepatic nodular regenerative hyperplasia (NRH) has been reported in patients treated with thiopurines for inflammatory bowel disease (IBD) (46, 47); however, only two studies reported TPMT genotype (48, 49). In both studies NRH was observed in patients who were heterozygous for the TPMT*3A allele. Further studies are needed to confirm the association between NRH and TPMT genotype.

The effects of NUDT15 variants on these long-term side effects of thiopurines are currently unknown.

High dose methotrexate is commonly given in combination with 6-mercaptopurine during consolidation therapy and re-inductions during maintenance therapy in patients with acute lymphoblastic leukemia. Through inhibition of purine de novo synthesis and enhancement of 6-mercaptopurine bioavailability, high dose methotrexate increases the incorporation of the cytotoxic metabolite of 6-mercaptopurine (6-thioguanine nucleotide) into DNA (50, 51). This interaction is enhanced with increasing levels of the methylated 6-mercaptopurine metabolite, MeTIMP (51). Additionally, the risk of significant bone-marrow suppression is increased if oral 6-mercaptopurine is co-administered with high dose methotrexate (52). Patients who are TPMT or NUDT15 deficient may experience life-threatening myelosuppression during combination therapy (53). Thus, reductions in the dose of concurrently given 6-mercaptopurine during high dose methotrexate therapy can significantly reduce the risk of severe myelotoxicity (50, 54).
RESOURCES TO INCORPORATE PHARMACOGENETICS INTO AN EHR WITH CDS

Clinical decision support (CDS) tools integrated within electronic health records (EHRs) can help guide clinical pharmacogenetics at the point of care (55-59). See https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt/ for resources to support the adoption of CPIC guidelines within an EHR. Based on the capabilities of various EHRs and local preferences, we recognize that approaches may vary across organizations. Our intent is to synthesize foundational knowledge that provides a common starting point for incorporating the use of TPMT and/or NUDT15 genotype results to guide thiopurine dosing and use in an EHR.

Effectively incorporating pharmacogenetic information into an EHR to optimize drug therapy should have some key attributes. Pharmacogenetic results, an interpreted phenotype, and a concise interpretation or summary of the result must be documented in the EHR (60, 61). To incorporate a phenotype in the EHR in a standardized manner, genotype test results provided by the laboratory must be consistently translated into an interpreted phenotype (Table 1, main manuscript). Because clinicians must be able to easily find the information, the interpreted phenotype may be documented as a problem list entry or in a patient summary section; these phenotypes are best stored in the EHR at the “person level” rather than at the date-centric “encounter level”. Additionally, results should be entered as standardized and discrete terms to facilitate using them to provide point-of-care CDS (55, 62).

Because pharmacogenetic results have lifetime implications and clinical significance, results should be placed into a section of the EHR that is accessible independent of the test result date to allow clinicians to quickly find the result at any time after it is initially placed in the EHR. To facilitate this process, CPIC is providing gene-specific information figures and tables that include full diplotype to phenotype tables, diagram(s) that illustrate how TPMT and/or NUDT15 pharmacogenetic test results could be entered into an EHR, example EHR consultation/genetic test interpretation language and widely
used nomenclature systems for genes relevant to the CPIC guideline (see https://www.pharmgkb.org/page/tpmtRefMaterials and https://www.pharmgkb.org/page/nudt15RefMaterials) (63, 64).

Point-of-care CDS should be designed to effectively notify clinicians of prescribing implications at any time after the test result is entered into the EHR. CPIC is also providing gene-drug specific tables that provide guidance to achieve these objectives with diagrams that illustrate how point-of-care CDS should be entered into the EHR, example pre- and post-test alert language, and widely used nomenclature systems for drugs relevant to the CPIC guideline (see https://cpicpgx.org/guidelines/guideline-for-thiopurines-and-tpmt/).
**FIGURE S1. IDEALIZED DEPICTIONS OF TPMT ACTIVITY IN ERYTHROCYTES FROM A NORMAL, HEALTHY, NON-TRANSFUSED POPULATION.** TPMT activity displays a trimodal frequency distribution (top) that corresponds to monogenic inheritance. Activity is generally directly related to TPMT protein levels, and inversely related to concentrations of active TGN (thioguanine nucleotide) metabolites.

*Rating Scheme for Quality of Evidence as per (196)*

ALL = acute lymphoblastic leukemia; AZA = azathioprine; CD = Crohn’s disease; RA = rheumatoid arthritis; IBD = inflammatory bowel disease; MP = mercaptopurine; TG = thioguanine; TPMT = thiopurine methyltransferase; 6-MMPN = 6-methylmercaptopurine nucleotides.
